Does the Femoral Cam Lesion Regrow After Osteoplasty for Femoroacetabular Impingement?

Two-Year Follow-up

Asheesh Gupta,* MD, John M. Redmond,* MD, Christine E. Stake,* MA,
Nathan A. Finch,* MA, Kevin F. Dunne,* BS, and Benjamin G. Domb,*†‡§ MD
Investigation performed at American Hip Institute, Westmont, Illinois, USA

Background: There are currently no studies that have examined the recurrence of the cam lesion after femoral neck osteoplasty for femoroacetabular impingement. Although patient-reported outcome (PRO) scores at midterm follow-up have shown continued success, the maintenance of a normalized alpha angle has not been shown radiographically.

Purpose: To assess the radiographic recurrence of cam deformity at 2-year follow-up after adequate decompression during the index hip arthroscopic procedure and correlate the findings with PRO scores. The hypothesis was that there would be no recurrence or regrowth of the cam deformity at the 2-year postoperative time point after adequate cam decompression during hip arthroscopic surgery.

Study Design: Case series; Level of evidence, 4.

Methods: Between March 2009 and January 2011, data were prospectively collected on all patients undergoing hip arthroscopic surgery with femoral neck osteoplasty. Minimum follow-up was 2 years, with radiographic images for review.

Results: A total of 47 patients met the inclusion criteria. The mean age of the participants at the start of the study was 37.18 years (range, 31.70-47.43 years). There were 28 men (59.57%) and 19 women (40.43%). The mean follow-up duration was 28.32 months (range, 24-41 months). The mean preoperative alpha angle (Dunn view) was 70° (range, 60°-97°), compared with 42.79° (range, 32°-50°) at 2 weeks postoperatively ($P < .0001$). The mean 2-year alpha angle was 42.72° (range, 32°-54°), which was not significantly different compared with the mean 2-week alpha angle ($P = .93$). Additionally, the mean femoral offset measurement was 3.7 mm (range, 0-9.9 mm) preoperatively and 7.8 mm (range, 0.3-13.9 mm) 2 weeks postoperatively ($P < .0001$). The mean 2-year postoperative femoral offset measurement was 8.0 mm (range, 2.4-12.8 mm), which was not significantly different compared with the mean 2-week femoral offset measurement ($P = .63$). All PRO scores were significantly improved at 3 months compared with preoperative scores and, except for visual analog scale score, continued to show improvement at 2-year follow-up.

Conclusion: There was no recurrence of cam deformity at 2 years after femoral neck osteoplasty for femoroacetabular impingement. PRO scores were improved at the 3-month and 2-year postoperative time points.

The morphologic characteristics of femoroacetabular impingement (FAI) were first characterized in 1936 by Smith-Petersen³⁸ in the setting of old slipped capital femoral epiphysis. With further study, the concept of FAI was defined to encompass excessive abutment of the femoral head-neck junction against the acetabular rim, leading to intra-articular cartilage delamination, labral injury, and early progression of arthritis.^{1,4,18,42} Our understanding of this disorder was further enhanced by the development of open surgical hip dislocation techniques described shortly thereafter in 2001.³¹ Open operative management has included surgical dislocation along with femoral head osteoplasty; acetabular chondral and labral lesions are usually addressed at the same time.¹⁶

Alternatively, arthroscopic procedures to treat FAI have also gained popularity.^{2,7,17,34,36} With regard to FAI, morphologic deformities may be either on the acetabular side (pincer impingement) or the femoral side (cam impingement), or both.²⁵ Cam lesions result from asphericity of the femoral head-neck junction, commonly located on the anterior-superior region. The contact of the cam lesion with the acetabular rim causes abrasion of the articular cartilage in the anterosuperior region of the acetabulum, with eventual tearing of the labrum in this region.^{11,26} Arthroscopic decompression of the cam lesion results in improvement of the radiographic alpha angle and normalization of internal rotation in impingement-related disease of the hip.²² Early skeptics of hip arthroscopic surgery were wary of the recurrence of the cam deformity. These concerns may have arisen after studies performed on the knee after anterior cruciate ligament reconstruction showing a thin layer of cortical bone forming over the femoral notchplasty site within 6 months of surgery.²⁹ Overgrowth of the notchplasty site by fibrocartilage has also been shown, resulting in graft impingement causing persistent effusion or lack of full extension.⁵ Although numerous studies have shown improvement in patient-reported outcome (PRO) scores with arthroscopic surgery, there is a subgroup of patients who experience persistent or recurrent symptoms postoperatively.^{9,24,41} Revision hip arthroscopic surgery has been performed primarily for the treatment of residual impingement deformity after index surgery.^{19,35} To our knowledge, no study has examined the possibility of recurrence of the cam lesion after adequate decompression during the index hip arthroscopic procedure.

The aim of this study was to assess the radiographic recurrence of cam deformity at 2-year follow-up after adequate decompression during the index hip arthroscopic procedure and to correlate this with PRO scores. Our hypothesis was that there would be no recurrence or regrowth of the cam deformity at the 2-year postoperative time point after adequate cam decompression during hip arthroscopic surgery.

MATERIALS AND METHODS

Patient Inclusion and Data Collection

We prospectively evaluated all patients at our institution who underwent hip arthroscopic surgery with a femoral neck osteoplasty for cam resection from March 2009 to January 2011 by the senior surgeon (B.G.D.). Inclusion criteria were a preoperative alpha angle $>60^\circ$ and a 2-week postoperative alpha angle $<50^\circ$ on the basis of radiographic examination on the Dunn view. Minimum follow-up was 2 years, with radiographic images for review. Specifically, all patients who had radiographic images available for measurement preoperatively, 2 weeks postoperatively, or 2 years postoperatively were included (Table 1). All patients at our institution undergo 2-week and 2-year postoperative radiography. Those who were lost to follow-up were excluded. Institutional review board approval was obtained.

TABLE 1
Inclusion and Exclusion Criteria^a

Inclusion Criteria	Exclusion Criteria
Preoperative alpha angle $>60^\circ$	Lack of Dunn profile radiographs at any time point measured
Postoperative alpha angle $<50^\circ$ at 2 weeks	No 2-year follow-up
Femoroplasty performed 2-year follow-up	

^aThe time points measured were the preoperative visit, 2 weeks postoperative, and 2 years postoperative.

Physical Examination

Detailed physical examinations were conducted on all hips before surgery, including assessment of passive range of motion and measurements of flexion, abduction, and internal and external rotation. Internal and external rotation was measured while the patient was in the supine position with both the hip and knee flexed at 90° . Anterior impingement test results were considered positive if pain was elicited in forced flexion combined with internal rotation of the hip, as previously described by Byrd.⁸ Lateral impingement test results were considered positive if symptoms were produced in forced abduction with external rotation. Posterior impingement test results were considered positive if pain was elicited with the hip passively extended by hanging over the examination table and then externally rotating the leg with the opposite limb in the neutral position. Evaluation of internal snapping of the iliopsoas tendon was performed as the hip was brought from a flexed, abducted, and externally rotated position into extension with internal rotation.⁸ All physical examinations were performed and documented in degrees by the senior surgeon in a clinical setting.

Imaging

Plain radiographs included an anteroposterior pelvic view, a Dunn view, a cross-table lateral view, and a false profile view.^{14,30,40} Measurements were made from these views, including the Tönnis angle (acetabular inclination angle) using the method described in Jessel et al,²¹ the lateral center edge angle of Wiberg,⁴⁴ joint space at its lowest point,⁴⁰ ischial prominence size in millimeters,⁴³ the cross-over sign,^{20,37,43} the alpha angle (Dunn view),³ and offset in millimeters.¹⁵ The Dunn view has been shown to best show the femoral neck/head contour.³⁰ In our practice, we flex the symptomatic hip to 90° and abduct 20° while maintaining a position of neutral rotation. The beam is directed at a point midway between the anterior superior iliac spine and the pubic symphysis. The x-ray tube-to-film distance is approximately 102 cm in a line directed perpendicular to the table. The alpha angle was measured on the Dunn view using the method described by Notzli for magnetic resonance imaging and modified by Meyer^{14,30,32} (Figure 1). Radiographic cam impingement was defined as an alpha angle $>60^\circ$. Hips were classified as having pincer

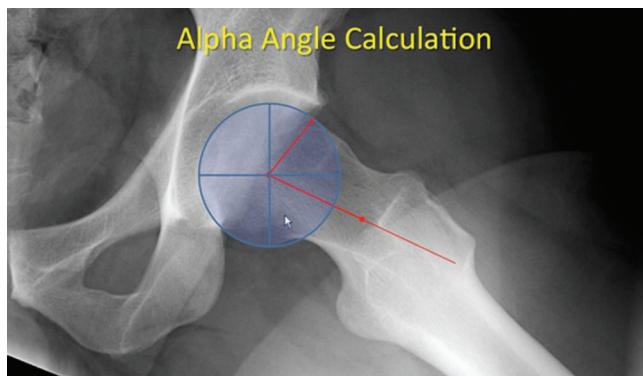

Figure 1. Alpha angle calculation.

impingement if they had a crossover sign, coxa profunda, or protrusion acetabula. The crossover sign size was quantified according to its percentage from the superior edge of the acetabulum; for instance, crossover at the middle of the acetabulum was quantified at 50%. The same orthopaedic surgeon (B.G.D.) made all measurements using a picture archiving and communication system. All radiographs were evaluated for arthritis and graded with Tönnis classification of osteoarthritis.⁴⁰ Magnetic resonance imaging was performed in all patients to evaluate for labral and articular cartilage injuries. Acetabular cartilage damage and labral tears were classified intraoperatively. Cartilage damage was classified according to the Outerbridge grading and acetabular labrum articular disruption classification systems.³³

Surgical Procedure

All hip arthroscopic procedures were performed at a tertiary referral center dedicated to hip arthroscopic surgery and preservation. All were performed in the modified supine position using a minimum of 2 portals (anterolateral and midanterior).^{6,23} The indications for surgery were labral tears with mechanical symptoms and failure of nonoperative treatment.

Intraoperative data were documented, including ligamentum teres, capsule, gluteus medius, femoral neck, acetabular rim, the presence and size of labral tears, and the presence and location of articular cartilage lesions. The Outerbridge and acetabular labrum articular disruption classifications were used to classify articular cartilage damage.³³

Bony pathologic lesions were corrected under fluoroscopic guidance. An acetabuloplasty was performed for pincer impingement, and a femoral neck osteoplasty was performed for cam impingement. Labral tears were repaired when possible; otherwise, they were selectively debrided until a stable labrum was achieved while preserving as much labrum as possible. Full-thickness cartilage damage was treated with debridement to create stable borders. Microfracture was performed at the surgeon's discretion according to the technique by Crawford et al¹² in cases in which bone was present after the bony decompression.

Surgical Outcomes Measure

All patients undergoing hip arthroscopic surgery were assessed with 4 PRO scores, including the modified Harris Hip Score, the Non-Arthritic Hip Score,¹⁰ the Hip Outcome Score—Activities of Daily Living, and the Hip Outcome Score—Sport-Specific Subscale. These scores were collected preoperatively and at 3-month and 2-year follow-up. We elected to use all 4 questionnaires because it has been reported that there is no conclusive evidence for the use of a single PRO questionnaire for patients undergoing hip arthroscopic surgery.^{27,39} Pain was estimated on a visual analog scale (VAS) ranging from 0 to 10 (10 being the worst), and satisfaction with surgery was rated on a scale ranging from 0 to 10.

Statistical Analysis

An a priori analysis was performed, and it was estimated that a clinically significant difference between alpha angles preoperatively and postoperatively was 23.2° , with an SD of the preoperative group of 12.4° .¹³ To obtain power of 0.80 or higher, we required a minimum of 12 hips in our study group (Cohen $d = 1.909$). A 2-tailed paired t test was used to assess differences between preoperative and postoperative scores. A dependent t test was used to compare the mean change in PRO score (change from preoperative to postoperative score). P values $< .05$ were considered significant. Statistical analysis was done with Microsoft Excel 2007 (Microsoft Corp) and IBM SPSS 12.0 for Windows (SPSS Inc).

RESULTS

Demographics

A total of 47 patients met the inclusion criteria. The average age of the study group was 37.18 years (range, 31.7–47.43 years) at the time of surgery. There were 28 men (59.57%) and 19 women (40.43%). The mean follow-up period was 28.32 months. All other demographics are presented in Table 2. At latest follow-up, all 47 patients were available.

Physical Examination Findings

Physical examination findings are presented in Table 3. Almost every patient had a positive anterior impingement sign ($n = 45$ [95.7%]), and some patients had a positive lateral impingement sign ($n = 29$ [61.7%]), with a posterior impingement sign as well ($n = 17$ [36.17%]).

Preoperative Imaging Findings

On radiographic examination, the mean joint space was 3.58 mm (range, 2 to 5.5 mm). The mean center edge angle was 30.16° (range, 16° to 55°). The mean crossover percentage was 15.51% (range, 0% to 50%), and the mean acetabular inclination was 5.61° (range, -11° to 23°) (Table 4).

TABLE 2
Patient Demographics^a

Variable	Value
Age, y	37.18 (31.7-47.43)
Men, No. (%)	28 (59.57)

Abduction, deg	43.15 (20-60)
Flexion, deg	122.77 (90-150)

^aValues are expressed as mean (range) unless otherwise indicated.

Operative Findings and Procedures

The main surgical procedures performed are summarized in Table 5. All patients underwent resection of cam with femoral neck osteoplasty for this study ($n = 47$ [100%]). Thirty-six patients underwent concomitant acetabuloplasty (76.6%), 37 underwent capsular release (78.7%), and 26 (55.32%) underwent labral repair.

Comparison of Alpha Angles and Femoral Offset on Dunn View

The mean alpha angle as measured on the Dunn radiographic view was 70° (range, 60° - 97°) preoperatively, compared with 42.79° (range, 32° - 50°) at 2-week follow-up ($P < .0001$) (Table 6). The mean 2-year alpha angle was 42.72° (range, 32° - 54°), which was not significantly different compared with the mean 2-week alpha angle ($P = .93$). When evaluating femoral offset, the mean value preoperatively was 3.7 mm (range, 0-9.9 mm). The mean 2-week postoperative femoral offset measurement was 7.8 mm (range, 0.3-13.9 mm), which was significantly different ($P < .0001$). The mean 2-year postoperative femoral offset measurement was 8.0 mm (range, 2.4-12.8 mm), which was not significantly different compared with the mean 2-week femoral offset measurement ($P = .63$).

Clinical Results

The mean preoperative hip-specific scores are shown in Figure 2. At the 3-month postoperative visit, all PRO scores and VAS score were significantly improved compared with preoperative scores ($P < .05$). When comparing 3-month with 2-year postoperative scores, there was no significant difference in all scores ($P > .05$), except for VAS score, which changed from 2.79 to 2.85 ($P < .01$). The modified Harris Hip Score improved from 58.43 preoperatively to 78.92 and 79.55 postoperatively at the 3-month and 2-year time points, respectively (Figure 2A). The Hip Outcome Score—Activities of Daily Living improved from 61.15 preoperatively to 80.48 and 80.65 postoperatively for the 3-month and 2-year time points (Figure 2B). The Hip Outcome Score—Sport-Specific Subscale improved from 37.38 preoperatively to 61.84 and 62.54 postoperatively for the 3-month and 2-year time points (Figure 2C). The Non-Arthritic Hip Score improved from 54.38 preoperatively to 78.47 and 78.70 postoperatively at the 3-month and 2-year time points (Figure 2D). The VAS score improved from 5.85 preoperatively to 2.79 at the 3-month postoperative visit. Interestingly, VAS score regressed to 2.85 at the 2-year time point, which was significant ($P < .001$) (Figure 2E). Last, patient satisfaction score improved from 7.85 to 7.91 from 3-month to 2-year follow-up postoperatively.

TABLE 6
Preoperative, 2-Week Postoperative, and 2-Year Postoperative Alpha Angles and Femoral Offset Measurements

Measurement	Preoperative	2-Week Postoperative	P Value ^a	2-Year Postoperative	P Value ^b

DISCUSSION

To our knowledge this is the first study assessing the radiographic recurrence of cam deformity at minimum 2-year follow-up. The results of our study offer new insights that there is no regrowth or recurrence of the cam deformity after femoral neck osteoplasty. We did show initial resection of the cam deformity on the basis of radiographic measurements 2-week postoperatively. These results are also validated by our PRO scores, which show statistically significant improvements for all scores at 3-month follow-up.

With the advent of improved arthroscopic techniques for FAI, the treatment of cam and pincer lesions has been shown to provide reproducible and successful outcomes.^{2,41} Femoral neck osteoplasty is not without its inherent risks. Mardones et al²⁸ concluded that resection of up to 30% of the anterolateral quadrant of the head-neck junction did not significantly alter the load-bearing capacity of the proximal part of the femur. They did find a significantly decreased amount of energy required to produce a fracture with a 30% resection. Wijdicks et al⁴⁵ also concluded that grade II (4.0-mm) and grade III (6.0-mm) cortical notching

with cam resection resulted in significant decreases in ultimate load and energy to failure compared with the intact group. In our study group, we did not report any iatrogenic femoral neck fractures during our 2-year follow-up period.

Incomplete resection of bony impingement can result in continued postoperative signs of FAI with poor patient-related outcomes. Heyworth et al¹⁹ showed that 79% of revision hip arthroscopic procedures in their study had unaddressed or undertreated bony impingement lesions. Philippon et al³⁵ published a case series on revision hip arthroscopic surgery showing that 36 of 37 patients had radiographic evidence of FAI. It must be noted that in both studies, there was no evidence of cam recurrence. The underlying pathology was not completely addressed during the primary procedure. In our study, we confirmed bony decompression of the femoral cam lesion at 2 weeks postoperatively and did not find any evidence of inadequate decompression.

Although we were able to determine that the adequately decompressed cam lesion does not reconstitute after femoral neck osteoplasty at the 2-year postoperative time point, there were certain limitations to our study. We present short-term follow-up, and it might be necessary to follow these patients at further time points to evaluate for recurrence of the cam deformity. Additionally, it is difficult to standardize patient positioning during the various radiographic views, which could possibly have led to errors in radiographic measurements. Finally, this study did not address whether patients who have residual cam lesions after decompression may have further regrowth after surgery. Another interesting area of study is the formation of cam deformity in younger patients with open physes to see if the deformity recurs with a continued high level of activity in the skeletally immature.

CONCLUSION

In our study, we found that the cam deformity does not recur at 2-year follow-up after adequate femoral neck osteoplasty for FAI. These results show that surgeons performing hip arthroscopic surgery for FAI can address the femoral neck cam deformity with osteoplasty with confidence of continued decompression of the bony lesion at 2 years if the initial decompression is adequate.
