Hip Impingement: Identifying and Treating a Common Cause of Hip Pain

GEOFFREY S. KUHLMAN, MD, Hinsdale Family Medicine Residency, Hinsdale, Illinois
BENJAMIN G. DOMB, MD, Hinsdale, Illinois

Femoroacetabular impingement, also known as hip impingement, is the abutment of the acetabular rim and the proximal femur. Hip impingement is increasingly recognized as a common etiology of hip pain in athletes, adolescents, and adults. It injures the labrum and articular cartilage, and can lead to osteoarthritis of the hip if left untreated. Patients with hip impingement often report anterolateral hip pain. Common aggravating activities include prolonged sitting, leaning forward, getting in or out of a car, and pivoting in sports. The use of flexion, adduction, and internal rotation of the supine hip typically reproduces the pain. Radiography, magnetic resonance arthrography, and injection of local anesthetic into the hip joint confirm the diagnosis. Pain may improve with physical therapy. Treatment often requires arthroscopy, which typically allows patients to resume premorbid physical activities. An important goal of arthroscopy is preservation of the hip joint. Whether arthroscopic treatment prevents or delays osteoarthritis of the hip is unknown. (Am Fam Physician. 2009;80(12):1429-1434, 1439-1440. Copyright © 2009 American Academy of Family Physicians.)

The hip is a ball-and-socket joint in which the articular surfaces of the femoral head and the acetabulum are lined with articular cartilage (Figure 1). The hip has a large range of motion in all planes, and is stabilized by a capsule, the surrounding muscles, and the labrum, which is a wedge-shaped cartilage structure that deepens the acetabulum and cushions the joint.

The differential diagnosis of hip pain is broad and includes conditions of the hip, lower back, and pelvis (Table 1). In recent years, notable progress has been made in the diagnosis and treatment of nonarthritic hip injuries. Labral tears and early cartilage damage are now recognized as common sources of pain. Femoroacetabular impingement (FAI) is recognized as a common etiology of hip injury. Many joint-preserving operations, such as labral debridement, labral repair, and decompression of impinging bone lesions, are performed arthroscopically and have shown improvements in pain and function.

Femoroacetabular Impingement

FAI is the abutment between the proximal femur and the rim of the acetabulum. It most often occurs anteriorly with flexion or rotation of the hip. FAI can begin in adolescence or adulthood. It usually progresses gradually and can injure the labrum and the articular cartilage of the hip, potentially limiting patients’ ability to exercise and causing pain with daily activities. FAI is a common cause of labral injury, and FAI with or without labral injury has been identified as an early cause of hip osteoarthritis.

Some persons are predisposed to impingement by bony abnormalities, which can be congenital or developmental. Excessive overhang of the anterior acetabulum causes

The FADIR test is the most sensitive physical examination test for FAI. Patients suspected of having FAI should have anteroposterior radiography of the pelvis and a modified Dunn view of the hip instead of standard hip radiography to assess for bony sources of impingement. Patients whose history and examination are consistent with FAI should undergo magnetic resonance arthrography to evaluate for labrum and articular cartilage injury, and diagnostic injection of local anesthetic to confirm that the source of pain is intra-articular. Patients with FAI pain refractory to conservative measures should be referred to an orthopedic surgeon for consideration of hip arthroscopy.

CT = computed tomography; FABER = flexion, abduction, and external rotation; MRI = magnetic resonance imaging.
pincer impingement, which generally occurs during flexion or internal rotation (Figure 2). Exostosis or bony overgrowth of the femoral head and neck causes cam impingement. Although most persons with FAI have such bony abnormalities, some patients with normal radiography findings may have FAI and a labral tear.

History

Patients with FAI typically have anterolateral hip pain. They often cup the anterolateral hip with the thumb and forefinger in the shape of a “C,” termed the C-sign (Figure 3). Pain is sharp when turning or pivoting, especially toward the affected side. It can worsen with prolonged sitting, rising from a seat, getting into or out of a car, or leaning forward. Pain is usually gradual and progressive.

Physical Examination

Physical examination of the hip begins with inspection, then palpation and assessment of range of motion. These steps and specific maneuvers for the hip are detailed in Table 2. The flexion, adduction, and internal rotation (FADIR) test is the most sensitive physical examination test for FAI (Figure 4). Because some of the maneuvers can cause minor discomfort in persons without hip joint pathology, testing the uninvolved side for comparison is prudent.

Diagnostic Testing

Radiography should be performed in patients in whom the history and physical examination are consistent with FAI. An anteroposterior (AP) view of the pelvis evaluates the hips for osteoarthritis; the acetabulum for dysplasia, overhang, or retroversion; the femoral head for osteonecrosis or remodeling; the sacroiliac joints for arthritis; and the lower lumbar spine. Because standard AP and lateral views of the hip can miss important abnormalities in patients with FAI, modified Dunn view radiography, in which the hip is flexed 90 degrees and abducted 20 degrees (Figure 5), should be ordered. This view is highly sensitive for detecting cam lesions and osteophytes on the anterior femoral neck.

Figure 2. Hip impingement, cam and pincer mechanisms. A pincer mechanism results from excessive overhang of the acetabulum, which causes the labrum to be impinged between the acetabulum and femoral head upon hip flexion. A cam mechanism occurs when exostosis along the femoral head and neck impinges the labrum against the acetabulum.

Figure 3. C-sign. Patients with femoroacetabular impingement often point to the area of pain by cupping the thumb and index finger in the shape of the letter C.

If concern for FAI persists, magnetic resonance arthrography is recommended to evaluate the labrum. Magnetic resonance imaging without arthrography has limited sensitivity (25 to 30 percent) for labral tears;
Arthrography improves sensitivity to 90 to 92 percent. Arthrography is usually accompanied by a diagnostic injection of local anesthetic (e.g., 10 mL of bupivacaine [Marcaine]). The patient should keep a pain diary for four days after the injection; relief of pain confirms an intra-articular origin of pain. The physician should keep in mind, however, that labral tears can be asymptomatic.

One retrospective study found that intra-articular injection of the hip with bupivacaine during magnetic resonance arthrography has 92 percent sensitivity, 97 percent specificity, and 90 percent accuracy for diagnosis of an intra-articular disorder. The absence of pain relief with the injection suggests an extra-articular source of pain, which theoretically rules out FAI. However, the anesthetic will not relieve pain in some patients because contrast media can irritate the joint. In these patients, a separate diagnostic injection with bupivacaine can be done.

Management
There are no published studies of nonsurgical treatment of FAI. Because FAI is typically symptomatic with activities of daily living, recommending rest from exercise is not likely to be beneficial. Analgesics have a limited role, and a trial of physical therapy is...
prudent. Treatment goals are to improve hip muscle flexibility and strength, posture, and other muscle or joint deficits identified in the physical examination. Patients with refractory cases should be referred to an orthopedic subspecialist for consideration of arthroscopy.

The goals of arthroscopy are to alleviate impingement, to repair or remove injured tissue, and to prevent or delay osteoarthritis. To alleviate impingement, pincer and cam lesions are removed and femoral offset is corrected, restoring bony alignment (Figure 6). Injured labral tissue is repaired or debrided. Studies of arthroscopic management of FAI are limited to case series.

Figure 5. Hip radiographs of a 50-year-old man with hip impingement. (A) The anteroposterior view is essentially normal. (B) The Dunn view shows a cam lesion on the superior aspect of the femoral neck (arrow). (C) Dunn view radiograph taken after arthroscopic osteoplasty of the cam lesion (arrow).

Figure 6. Pincer lesion. (A) Modified Dunn view of a hip with a pincer lesion (arrow). (B) Postoperative radiograph shows that the pincer lesion (arrow) is reduced.
Hip Impingement

One study of 45 professional athletes undergoing arthroscopy for FAI showed that 42 (93 percent) returned to professional sports.\textsuperscript{\ref{16}} 
A study of 100 patients with FAI yielded good or excellent results in 75 percent of patients at one year.\textsuperscript{\ref{17}} Another study of 19 patients showed that 16 (84 percent) improved.\textsuperscript{\ref{18}}

Predictors of favorable outcomes from arthroscopy include mechanical symptoms (e.g., locking, catching, popping) and sharp pain. The presence of osteoarthritis reduces the likelihood of a positive result.\textsuperscript{\ref{16,19}}

Risks of surgery include neurovascular injury, infection, deep venous thrombosis, and heterotopic bone formation. Theoretic risks unique to arthroscopic treatment of FAI are femoral neck fracture and avascular necrosis of the femoral head, but few cases have been reported. It is hypothesized that arthroscopic treatment of FAI can prevent or delay the onset or progression of osteoarthritis of the hip, but this has yet to be demonstrated with long-term clinical follow-up.
